Abstract

The wobbling motion excited on triaxial superdeformed nuclei is studied in terms of the cranked shell model plus random phase approximation. Firstly, by calculating at a low rotational frequency the γ -dependence of the three moments of inertia associated with the wobbling motion, the mechanism of the appearance of the wobbling motion in positive- γ nuclei is clarified theoretically — the rotational alignment of the $\pi i_{13/2}$ quasiparticle(s) is the essential condition. This indicates that the wobbling motion is a collective motion that is sensitive to the single-particle alignment. Secondly, we prove that the observed unexpected rotational-frequency dependence of the wobbling frequency is an outcome of the rotational-frequency dependent dynamical moments of inertia.

I. INTRODUCTION

Deformation of the nuclear shape from spherical symmetric one has long been one of the most important issues in nuclear structure physics. Among them, searches for evidences of the triaxial (Y_{22} or γ) one have been pursued long time, for example, the even-odd energy staggering in the low-spin part of the γ bands [1], the signature dependence of the energy spectra and the $E2/M1$ transition rates in medium-spin odd-odd and odd- A nuclei [2, 3, 4], properties of the K isomers [5, 6], and so on. But their results have not been conclusive; making a clear distinction between the static and the dynamic (vibrational) ones has not been successful up to now. Theoretically, appearance of the wobbling motion, which is well-known in classical mechanics of asymmetric tops [7] and whose quantum analog was discussed in terms of a rotor model about thirty years ago [8], is a decisive evidence of static triaxial deformations. Subsequently its microscopic descriptions were developed by several authors [9, 10]. Since the small-amplitude wobbling mode carries the same quantum numbers, parity $\pi = +$ and signature $\alpha = 1$, as the odd-spin members of the γ band, Ref.[11] anticipated that it would appear as a high-spin continuation of the γ band, but it has not been resolved that in what nuclei, at what spins, and with what γ wobbling modes would be observed.

Shimizu and Matsuyanagi [12] and Onishi [13] performed extensive numerical calculations for normally-deformed Er isotopes with relatively small $|\gamma|$. Matsuzaki [14], Shimizu and Matsuzaki [15], and Horibata and Onishi [16] also studied ^{182}Os with relatively large negative- γ but their correspondence to experimental information has not been very clear.

These studies indicate the necessity of high-spin states in stably and strongly γ -deformed nuclei. Bengtsson studied high-spin states around ^{164}Hf [17] and found systematic existence of the TSD (triaxial super- or strongly deformed) states with $\epsilon_2 \sim 0.4$ and $|\gamma| \sim 20^\circ$. This confirmed the discussion on the shell gap at $N = 94$ in Ref.[18], the work in which the yrast TSD band in ^{163}Lu was reported; and in 2000 an excited TSD band was observed in this nucleus and from the strengths of the interband $E2$ transition rates this was unambiguously identified with the wobbling motion [19]. This data was analyzed by using a particle-rotor model [20] and the $E2$ transition rates were reproduced well. Subsequently TSD bands were found in some Lu and Hf isotopes and wobbling excitations were observed also in $^{165,167}\text{Lu}$ [21, 22]. A close look at these data, however, tells us that the sign of their γ -

deformation seems to contradict to an irrotational motion and that the unexpected behavior of the wobbling frequency has not been explained yet.

Thus in the preceding Rapid Communication [23] we presented an answer to these problems. In the present paper, after summarizing the discussion there we extend numerical analyses to elucidate it. An emphasis is put on the behavior of the calculated dynamic moments of inertia.

II. WOBBLING MOTION IN TERMS OF THE RANDOM PHASE APPROXIMATION

We start from a one-body Hamiltonian in the rotating frame,

$$h' = h - \hbar\omega_{\text{rot}}J_x, \quad (1)$$

$$h = h_{\text{Nil}} - \Delta_\tau(P_\tau^\dagger + P_\tau) - \lambda_\tau N_\tau, \quad (2)$$

$$h_{\text{Nil}} = \frac{\mathbf{p}^2}{2M} + \frac{1}{2}M(\omega_x^2 x^2 + \omega_y^2 y^2 + \omega_z^2 z^2) \\ + v_{ls}\mathbf{l} \cdot \mathbf{s} + v_{ll}(\mathbf{l}^2 - \langle \mathbf{l}^2 \rangle_{N_{\text{osc}}}). \quad (3)$$

In Eq.(2), $\tau = 1$ and 2 stand for neutron and proton, respectively, and chemical potentials λ_τ are determined so as to give correct average particle numbers $\langle N_\tau \rangle$. The oscillator frequencies in Eq.(3) are expressed by the quadrupole deformation parameters ϵ_2 and γ in the usual way. They are treated as parameters as well as pairing gaps Δ_τ . The orbital angular momentum $\mathbf{l}$ in Eq.(3) is defined in the singly-stretched coordinates $x'_k = \sqrt{\frac{\omega_k}{\omega_0}}x_k$, with $k = 1 - 3$ denoting $x - z$, and the corresponding momenta. By diagonalizing h' at each ω_{rot} , we obtain quasiparticle (QP) orbitals and the nuclear yrast (0QP) state. Since h' conserves parity π and signature α , nuclear states can be labeled by them. Nuclear states with QP excitations are obtained by exchanging the QP energy and wave functions such as

$$(-e'_\mu, \mathbf{V}_\mu, \mathbf{U}_\mu) \rightarrow (e'_{\bar{\mu}}, \mathbf{U}_{\bar{\mu}}, \mathbf{V}_{\bar{\mu}}), \quad (4)$$

where $\bar{\mu}$ denotes the signature partner of μ .

We perform the random phase approximation (RPA) to the residual pairing plus doubly-stretched quadrupole-quadrupole ($Q'' \cdot Q''$) interaction between QPs. Since we are interested in the wobbling motion that has a definite quantum number, $\alpha = 1$, only two components

out of five of the $Q'' \cdot Q''$ interaction are relevant. They are given by

$$H_{\text{int}}^{(-)} = -\frac{1}{2} \sum_{K=1,2} \kappa_K^{(-)} Q_K''^{(-)\dagger} Q_K''^{(-)}, \quad (5)$$

where the doubly-stretched quadrupole operators are defined by

$$Q_K'' = Q_K(x_k \rightarrow x_k'' = \frac{\omega_k}{\omega_0} x_k), \quad (6)$$

and those with good signature are

$$Q_K^{(\pm)} = \frac{1}{\sqrt{2(1 + \delta_{K0})}} (Q_K \pm Q_{-K}). \quad (7)$$

The residual pairing interaction does not contribute because P_τ is an operator with $\alpha = 0$.

The equation of motion,

$$\left[h' + H_{\text{int}}^{(-)}, X_n^\dagger \right]_{\text{RPA}} = \hbar \omega_n X_n^\dagger, \quad (8)$$

for the eigenmode

$$X_n^\dagger = \sum_{\mu < \nu}^{(\alpha=\pm 1/2)} \left(\psi_n(\mu\nu) a_\mu^\dagger a_\nu^\dagger + \varphi_n(\mu\nu) a_\nu a_\mu \right) \quad (9)$$

leads to a pair of coupled equations for the transition amplitudes

$$T_{K,n} = \left\langle \left[Q_K^{(-)}, X_n^\dagger \right] \right\rangle. \quad (10)$$

Then, by assuming $\gamma \neq 0$, this can be cast [10] into the form

$$\begin{aligned} (\omega_n^2 - \omega_{\text{rot}}^2) \left[\omega_n^2 - \omega_{\text{rot}}^2 \frac{(\mathcal{J}_x - \mathcal{J}_y^{(\text{eff})}(\omega_n)) (\mathcal{J}_x - \mathcal{J}_z^{(\text{eff})}(\omega_n))}{\mathcal{J}_y^{(\text{eff})}(\omega_n) \mathcal{J}_z^{(\text{eff})}(\omega_n)} \right] \\ = 0, \end{aligned} \quad (11)$$

which is independent of $\kappa_K^{(-)}$ s. This expression proves that the spurious (Nambu–Goldstone) mode given by the first factor and all normal modes given by the second are decoupled from each other. Here $\mathcal{J}_x = \langle J_x \rangle / \omega_{\text{rot}}$ as usual and the detailed expressions of $\mathcal{J}_{y,z}^{(\text{eff})}(\omega_n)$ are given in Refs.[10, 14, 15]. Among normal modes, one obtains

$$\omega_{\text{wob}}^2 = \omega_{\text{rot}}^2 \frac{(\mathcal{J}_x - \mathcal{J}_y^{(\text{eff})}(\omega_{\text{wob}})) (\mathcal{J}_x - \mathcal{J}_z^{(\text{eff})}(\omega_{\text{wob}}))}{\mathcal{J}_y^{(\text{eff})}(\omega_{\text{wob}}) \mathcal{J}_z^{(\text{eff})}(\omega_{\text{wob}})}, \quad (12)$$

by putting $\omega_n = \omega_{\text{wob}}$. Note that this gives a real excitation only when the right-hand side is positive and it is non-trivial whether a collective solution appears or not. Evidently this

coincides with the form derived by Bohr and Mottelson in a rotor model [8] and known in classical mechanics [7], aside from the crucial feature that the moments of inertia are ω_{rot} -dependent in the present case.

One drawback in our formulation is that our $\mathcal{J}_x$ tends to be larger than corresponding experimental values because of the spurious velocity dependence of the Nilsson potential as discussed in Refs.[24, 25]. A remedy for this was discussed there but that for $\mathcal{J}_{y,z}^{(\text{eff})}$ has not been devised yet. Therefore we assume for the present a similar discussion holds for the latter and accordingly the ratio $\mathcal{J}_{y,z}^{(\text{eff})}(\omega_{\text{wob}})/\mathcal{J}_x$ which actually determines ω_{wob} is more reliable than their absolute magnitudes.

Interband electric quadrupole transitions between the n -th excited band and the yrast are given as

$$B(E2 : I_n \rightarrow (I \pm 1)_{\text{yrast}}) = \frac{1}{2} \left(T_{1,n}^{(E)} \pm T_{2,n}^{(E)} \right)^2, \quad (13)$$

in terms of

$$T_{K,n}^{(E)} = e \frac{Z}{A} T_{K,n}. \quad (14)$$

They will be abbreviated to $B(E2)_{\text{out}}$ later for simplicity. In-band ones are given as

$$B(E2 : I \rightarrow I - 2) = \frac{1}{2} \left(\frac{\sqrt{3}}{2} \langle Q_0^{(+)(E)} \rangle + \frac{1}{2} \langle Q_2^{(+)(E)} \rangle \right)^2, \quad (15)$$

in terms of

$$\langle Q_K^{(+)(E)} \rangle = e \frac{Z}{A} \langle Q_K^{(+)} \rangle, \quad (16)$$

and assumed to be common to all bands. They will be abbreviated to $B(E2)_{\text{in}}$. Here we adopted a high-spin approximation [26]. The transition quadrupole moment Q_t is extracted from $B(E2)_{\text{in}}$ by the usual rotor-model prescription.

To compare collectivities of these two types of $E2$ transitions, we introduce a pair of deformation parameters

$$\begin{aligned} R^2 \alpha_y &= \sqrt{\frac{15}{16\pi}} \langle x^2 - z^2 \rangle = \left\langle \frac{1}{2} Q_2^{(+)} - \frac{\sqrt{3}}{2} Q_0^{(+)} \right\rangle, \\ R^2 \alpha_z &= \sqrt{\frac{15}{16\pi}} \langle x^2 - y^2 \rangle = \langle Q_2^{(+)} \rangle. \end{aligned} \quad (17)$$

Then it is evident that the in-band one is expressed as

$$B(E2 : I \rightarrow I - 2) = \frac{1}{2} R^4 \left(\alpha_y^{(E)} - \alpha_z^{(E)} \right)^2. \quad (18)$$

As for the interband ones, by expanding $Q_K^{(-)}$ by $X_n^\dagger$ s and X_n s, where n runs both normal modes and the Nambu–Goldstone mode $X_{\text{NG}}^\dagger = \frac{1}{\sqrt{2I}}(J_z + iJ_y)$, we obtain from $[Q_1^{(-)}, Q_2^{(-)}] = 0$ a kind of sum rule

$$\sum_{n \neq \text{NG}} T_{1,n} T_{2,n} = -\frac{2}{I} R^4 \alpha_y \alpha_z. \quad (19)$$

Consecutively introducing the ratios of the dynamic to static deformations,

$$\begin{aligned} r_{y,n} &= \frac{T_{1,n}}{2R^2 \alpha_y}, \\ r_{z,n} &= -\frac{T_{2,n}}{2R^2 \alpha_z}, \end{aligned} \quad (20)$$

the sum rule above reads

$$\sum_{n \neq \text{NG}} r_{y,n} r_{z,n} = \frac{1}{2I}. \quad (21)$$

The dynamic amplitudes $T_{K,n}$ describe shape fluctuations associated with the vibrational motion in the uniformly rotating frame. Transformation to the body-fixed (Principal-Axis) frame [10] turns the shape fluctuation into the fluctuation of the angular momentum vector, i.e., the wobbling motion. This transformation relates the ratios, $r_{y,n}$ and $r_{z,n}$, to the moments of inertia [15]:

$$\begin{aligned} r_{y,n} &= c_n \frac{1}{\sqrt{2I}} \left(\frac{W_{z,n}}{W_{y,n}} \right)^{1/4}, \\ r_{z,n} &= \sigma_n c_n \frac{1}{\sqrt{2I}} \left(\frac{W_{y,n}}{W_{z,n}} \right)^{1/4}, \end{aligned} \quad (22)$$

where c_n is a real amplitude that relates the dynamic amplitude $T_{K,n}$ and the moment of inertia, σ_n is the sign of $(\mathcal{J}_x - \mathcal{J}_y^{(\text{eff})})$ (so $\sigma_n > 0$ for wobbling-like RPA solutions), and

$$\begin{aligned} W_{y,n} &= 1/\mathcal{J}_z^{(\text{eff})}(\omega_n) - 1/\mathcal{J}_x, \\ W_{z,n} &= 1/\mathcal{J}_y^{(\text{eff})}(\omega_n) - 1/\mathcal{J}_x. \end{aligned} \quad (23)$$

Thus, the interband $B(E2)$ is rewritten as,

$$\begin{aligned} &B(E2 : I_n \rightarrow (I \pm 1)_{\text{yrast}}) \\ &= \frac{1}{I} R^4 c_n^2 \left[\alpha_y^{(E)} \left(\frac{W_{z,n}}{W_{y,n}} \right)^{1/4} \mp \sigma_n \alpha_z^{(E)} \left(\frac{W_{y,n}}{W_{z,n}} \right)^{1/4} \right]^2, \end{aligned} \quad (24)$$

which coincides with the formula given by the rotor model [8], except for the appearance of the amplitude c_n and sign σ_n . Substituting the ratios, $r_{y,n}$ and $r_{z,n}$, into Eq.(21), one finds that the amplitudes should satisfy

$$\sum_{n \neq \text{NG}} \sigma_n c_n^2 = 1. \quad (25)$$

This form of sum rule clearly indicates that the amplitude c_n is a microscopic correction factor quantifying the collectivity of the wobbling motion, for which $c_n^2 \simeq 1$ means the full collectivity and reproduces the results of the macroscopic rotor model in both the energy and the interband $B(E2)$ values.

III. NUMERICAL CALCULATION AND DISCUSSION

A. Summary of the preceding study

Since the first experimental confirmation of the wobbling excitation in ^{163}Lu [19], $\gamma \simeq +20^\circ$ has been widely accepted as the shape of the TSD states in this region. This is predominantly because the calculated energy minimum for $\gamma \simeq +20^\circ$ is deeper than that for $\gamma \simeq -20^\circ$ [17] according to the shape driving effect of the aligned $\pi i_{13/2}$ quasiparticle. The recent precise measurements of Q_t [27] also support this. On the other hand, the sign of γ -deformation leads different consequences on moments of inertia, which are directly connected to the excitation energy of the wobbling mode through the wobbling frequency formula [8], c.f. Eq.(12). Since the RPA is a microscopic formalism, no distinction between the collective rotation and the single-particle degrees of freedom has been made.

Therefore, the moments of inertia calculated in our RPA formalism in sect.II are those for rotational motions of the whole system. In contrast, the macroscopic irrotational-like moments of inertia are often used in the particle-rotor calculations, where $\mathcal{J}_y > \mathcal{J}_x \gg \mathcal{J}_z$ for $\gamma \simeq +20^\circ$ and they lead to an imaginary wobbling frequency ω_{wob} . It is, however, noted that the moments of inertia of the particle-rotor model are those of the rotor and no effect of the single-particle alignments is included, so that they do not necessarily correspond to those calculated in our RPA formalism.

In the preceding paper [23] we have performed microscopic RPA calculations without dividing the system artificially into the rotor and particles. That work proved that for the

calculated moment of inertia, $\mathcal{J}_x = \langle J_x \rangle / \omega_{\text{rot}}$, the contribution from the aligned QP(s), $\Delta\mathcal{J}_x = i_{\text{QP}} / \omega_{\text{rot}}$ with i_{QP} being the aligned angular momentum, is superimposed on an irrotational-like moment of inertia ($\mathcal{J}_y > \mathcal{J}_x$) of the “core”. Consequently the total $\mathcal{J}_x$ is larger than $\mathcal{J}_y$, which makes wobbling excitation in $\gamma > 0$ nuclei possible.

The second consequence of the formulation adopted in Ref.[23] is that the three moments of inertia are automatically ω_{rot} -dependent even when the mean-field parameters are fixed constant. This is essential in order to explain the observed ω_{rot} -dependence of ω_{wob} — *decreasing* as ω_{rot} increases. Otherwise ω_{wob} is proportional to ω_{rot} .

Another important feature of the data is that the interband $B(E2)$ values between the wobbling and the yrast TSD bands are surprisingly large. Our RPA wave function gave extremely collective $B(E2)_{\text{out}}$ that gathered $|c_{n=\text{wob}}| \simeq 0.6 - 0.8$ in the sum rule (Eq.(25)) but the result accounted for only about one half of the measured one.

To elucidate these findings more, in the following we extend our numerical analyses putting a special emphasis on the γ -dependence of the moments of inertia in subsect.III B. Dependence on other parameters is also studied in detail. Features in common and different between even-even and odd- A nuclei are also pointed out. In subsect.III C, we discuss ω_{rot} -dependence. In subsect.III D, characteristics of $B(E2)_{\text{out}}$ are discussed. Calculations are performed in five major shells; $N_{\text{osc}} = 3 - 7$ for neutrons and $N_{\text{osc}} = 2 - 6$ for protons. The strengths v_{ls} and v_{ll} in Eq.(3) are taken from Ref.[28].

B. Dependence on the mean-field parameters γ , ϵ_2 , and Δ

1. The even-even nucleus ^{168}Hf

Hafnium-168 is the first even-even nucleus in which TSD bands were observed [29]. In this nucleus three TSD bands were observed but interband γ -rays connecting them have not been observed yet. This means that the character of the excited bands has not been established, although we expect at least one of them is wobbling excitation. An important feature of the data is that the average transition quadrupole moment was determined as $Q_t = 11.4^{+1.1}_{-1.2}$ eb. This imposes a moderate constraint on the shape. Referring to the weak parameter dependence discussed later, we choose $\epsilon_2 = 0.43$, $\gamma = 20^\circ$, and $\Delta_n = \Delta_p = 0.3$ MeV, which reproduce the observed Q_t , as a typical mean-field parameter set.

First we study the dependence of various quantities on γ and other mean-field parameters at $\hbar\omega_{\text{rot}} = 0.25$ MeV. Around this frequency the $(\pi i_{13/2})^2$ alignment that is essential for making wobbling excitation in $\gamma > 0$ nuclei possible is completed and therefore the wobbling motion is expected to emerge above this frequency (see Fig.7 shown later).

Figure 1 shows dependence on γ calculated with keeping $\epsilon_2 = 0.43$ and $\Delta_n = \Delta_p = 0.3$ MeV. Figure 1(a) graphs the calculated excitation energy in the rotating frame, $\hbar\omega_{\text{wob}}$. As γ comes close to 0 (symmetric about the z axis) and -60° (symmetric about the y axis), ω_{wob} approaches 0, see Eq.(12). We did not obtain any low-lying RPA solutions at around $\gamma = 40^\circ$ whereas a collective solution appears again for $50^\circ \leq \gamma \leq 60^\circ$.

FIG. 1: Triaxiality dependence of (a) excitation energy of the wobbling motion, (b) three moments of inertia associated with it, (c) expectation values of angular momenta in the yrast state, and (d) quadrupole transition amplitudes between the wobbling and the yrast states in ^{168}Hf , calculated at $\hbar\omega_{\text{rot}} = 0.25$ MeV with $\epsilon_2 = 0.43$ and $\Delta_n = \Delta_p = 0.3$ MeV.

Figure 1(b) shows the calculated moments of inertia. Their γ -dependence resembles the irrotational, the so-called γ -reversed, and the rigid-body moments of inertia, in $\gamma < 0$, $0 < \gamma < 40^\circ$, and $50^\circ \leq \gamma \leq 60^\circ$, respectively. These model moments of inertia are given by

$$\mathcal{J}_k^{\text{irr}} = 4B\beta^2 \sin^2 \left(\gamma + \frac{2}{3}\pi k \right), \quad (26)$$

$$\mathcal{J}_k^{\text{rev}} = 4B\beta^2 \sin^2 \left(-\gamma + \frac{2}{3}\pi k \right), \quad (27)$$

and

$$\mathcal{J}_k^{\text{rig}} = \mathcal{J}_0 \left(1 - \sqrt{\frac{5}{4\pi}} \beta \cos \left(\gamma + \frac{2}{3}\pi k \right) \right), \quad (28)$$

where $k = 1 - 3$ denote the $x - z$ principal axes, B the irrotational mass parameter, $\mathcal{J}_0$ the rigid moment of inertia in the spherical limit, and β is a deformation parameter like ϵ_2 . The γ -reversed moment of inertia was introduced to describe positive- γ rotations in the particle-rotor model [3] but its physical meaning has not been very clear; in particular, it does not fulfill the quantum-mechanical requirement that the rotations about the symmetry axis should be forbidden. We have clarified in the preceding paper [23] that the contributions from aligned quasiparticles superimposed on irrotational-like moments of inertia ($\mathcal{J}_x < \mathcal{J}_y$) can realize $\mathcal{J}_x > \mathcal{J}_y$ and this is the very reason why the wobbling excitation (see Eq.(12)) appears in positive- γ nuclei. We also discussed that multiple alignments could eventually lead to a rigid-body-like moment of inertia. Figure 1(c) indicates that, in the present calculation in which configuration is specified as the adiabatic quasiparticle vacuum at each ω_{rot} , two $\pi i_{13/2}$ protons align for $\gamma > 0$ as mentioned above while they have not fully aligned for $\gamma < 0$ at this ω_{rot} . In other words, these figures cover the both regions in which the $(\pi i_{13/2})^2$ alignment is necessary ($\gamma > 0$) and that is not necessary ($\gamma < 0$) for obtaining wobbling excitations. This aligned angular momentum determines the overall γ -dependence of $\mathcal{J}_x$ in Fig.1(b). As for the neutron part, corresponding to the disappearance of the solution at around $\gamma = 40^\circ$, the expectation value of the neutron angular momentum, $\langle J_x \rangle_n$, drops around this region.

To look at this more closely, we investigate the Nilsson single-particle diagram at $\omega_{\text{rot}} = 0$. Figure 2(a) graphs neutron single-particle energies for $0 \leq \epsilon_2 \leq 0.43$ with $\gamma = 0$, while Fig.2(b) for $0 \leq \gamma \leq 60^\circ$ with $\epsilon_2 = 0.43$. The chemical potential that gives correct neutron number $N = 96$ for $\gamma > 0$ at $\hbar\omega_{\text{rot}} = 0.25$ MeV is also drawn in the latter. This figure clearly shows that with this ϵ_2 a shell gap exists for $\gamma \lesssim 20^\circ$ at $N = 96$. And by comparing this with Fig.1 we see that the dropping of $\langle J_x \rangle_n$ is a consequence of the deoccupation of the orbital that is [651 1/2] at $\gamma = 0$ (hereafter simply referred to as the [651 1/2] orbital even at $\gamma \neq 0$) originating from the mixed $(g_{9/2}-i_{11/2})$ spherical shell. Figure 2(b) also explains the

reason why the wobbling excitation revives at around $\gamma = 50^\circ$ again; the occupation of other oblate-favoring orbitals such as $[503\ 7/2]$ makes it possible and leads to a rigid-body-like behavior of the moments of inertia. Figures 2(c) and (d) are corresponding ones for protons. This indicates that the proton shell gap is robuster.

FIG. 2: Nilsson single-particle energy diagrams at $\omega_{\text{rot}} = 0$, (a) for $0 \leq \epsilon_2 \leq 0.43$ with $\gamma = 0$, and (b) for $0 \leq \gamma \leq 60^\circ$ with $\epsilon_2 = 0.43$ for neutrons. (c) and (d) are corresponding ones for protons. Solid and dashed curves represent even and odd parity orbitals, respectively. Asymptotic quantum numbers of some important orbitals are explicitly indicated. Chemical potentials that give particle numbers $N = 96$ and $Z = 72$ for $\gamma = +20^\circ$ at $\hbar\omega_{\text{rot}} = 0.25$ MeV are also indicated in (b) and (d).

Figure 1(d) graphs the quadrupole transition amplitudes T_K ($K = 1, 2$) associated with the wobbling mode. (T_K corresponds to $(-1)^{K-1}\mathcal{Q}_K$ in Ref.[15].) This shows that their relative sign changes with that of γ as discussed in Refs.[14, 15]. This feature can be understood as: $\gamma \sim 0$ is the γ -vibrational region because the $K = 2$ component is dominant (see also $\mathcal{J}_x \simeq \mathcal{J}_y^{(\text{eff})}$ and $\mathcal{J}_z^{(\text{eff})} \simeq 0$ in Fig.1(b)), and the mixing of the $K = 1$ component due to triaxiality and rotation gives rise to the character of the wobbling motion. This relative sign leads to a selection rule of the interband transition probabilities $B(E2)_{\text{out}}$ [15]. In the present case we obtain $B(E2 : I \rightarrow I - 1)_{\text{out}} \gtrless B(E2 : I \rightarrow I + 1)_{\text{out}}$ for $\gamma \gtrless 0$, and typically

their ratio to the in-band ones is $B(E2 : I \rightarrow I - 1)_{\text{out}}/B(E2 : I \rightarrow I - 2)_{\text{in}} \sim 0.1$.

Figure 3 shows dependence on ϵ_2 calculated with keeping $\gamma = 20^\circ$ and $\Delta_n = \Delta_p = 0.3$ MeV. The steep rises at around $\epsilon_2 = 0.33$ in Figs.3(a) and (b) indicate the necessity of the $(\pi i_{13/2})^2$ (the $[660\ 1/2]$ orbital in Fig.2(c)) alignment for the appearance of the wobbling mode although the critical value of ϵ_2 itself is frequency dependent. Aside from this, ω_{wob} is almost constant in the calculated range. The slight increase at around $\epsilon_2 = 0.4$ stems from the occupation of the $\nu[651\ 1/2]$ orbital. We have confirmed that in this case the $(\nu j_{15/2})^2$ alignment at around $\epsilon_2 = 0.47$ seen in Fig.3(b) does not affect ω_{wob} visibly since $\Delta\mathcal{J}_y^{(\text{eff})}$ in this case is almost the same as $\Delta\mathcal{J}_x$ although its reason is not clear. Figure 3(c) graphs Q_t . This figure indicates that the chosen shape $\epsilon_2 = 0.43$ and $\gamma = 20^\circ$ reproduces the measured Q_t .

FIG. 3: Deformation dependence of (a) excitation energy of the wobbling motion, (b) expectation values of angular momenta in the yrast state, and (c) transition quadrupole moment in the yrast state in ^{168}Hf , calculated at $\hbar\omega_{\text{rot}} = 0.25$ MeV with $\gamma = 20^\circ$ and $\Delta_n = \Delta_p = 0.3$ MeV.

Figure 4(a) shows dependence on the pairing gaps. Since we do not have detailed information about the gaps, we assume $\Delta_n = \Delta_p$ for simplicity. This figure shows that the dependence on the gaps is weak unless they are too large. Since the static pairing gap Δ

is expected to be small, say, $\Delta \leq 0.6$ MeV, in the observed frequency range, ω_{wob} is not sensitive to the value of Δ . This is a striking contrast to the β and γ vibrations; it is well known that pairing gaps are indispensable for them. Here we note that the behavior of the ω_{wob} correlates well with $\langle J_x \rangle_p$ presented in Fig.4(b).

FIG. 4: Pairing gap dependence of (a) excitation energy of the wobbling motion and (b) expectation values of angular momenta in the yrast state in ^{168}Hf , calculated at $\hbar\omega_{\text{rot}} = 0.25$ MeV with $\epsilon_2 = 0.43$ and $\gamma = 20^\circ$. $\Delta_n = \Delta_p$ is assumed for simplicity.

2. The odd- A nucleus ^{167}Lu

Next we study ^{167}Lu in a way similar to the preceding ^{168}Hf case. We choose $\gamma = 20^\circ$ and $\Delta_n = \Delta_p = 0.3$ MeV as representative mean-field parameters as above. As for ϵ_2 , however, we examined various possibilities because Q_t has not been measured in this nucleus. Since the sensitive ϵ_2 -dependence through the occupation of the $\nu[651\ 1/2]$ orbital appears only at $\hbar\omega_{\text{rot}} > 0.4$ MeV and therefore the “band-head” properties do not depend on ϵ_2 qualitatively, first we discuss them adopting $\epsilon_2 = 0.43$ in order to look at the difference between the even-even and the odd- Z cases.

Figure 5 shows dependence on γ at $\hbar\omega_{\text{rot}} = 0.25$ MeV with keeping $\epsilon_2 = 0.43$ and $\Delta_n = \Delta_p = 0.3$ MeV constant. Figure 5(a) graphs ω_{wob} . In the $\gamma > 0$ region, the solution is quite similar to the ^{168}Hf case. In the $\gamma < 0$ region, that for $-60^\circ \leq \gamma \lesssim -30^\circ$ is quite similar again but for $-30^\circ \lesssim \gamma < 0$ its character is completely different. In this region the presented solution is the lowest in energy and becoming collective gradually as γ decreases. The largeness of ω_{wob} corresponds to that of $\mathcal{J}_x - \mathcal{J}_y^{(\text{eff})}$ in Fig.5(b). Comparison of Figs.5(c)

and 1(c) certifies that the alignment of the $\pi i_{13/2}$ quasiparticle(s) is almost complete for $\gamma > 0$ whereas less for $\gamma < 0$. This produces quantitative even-odd differences as explained below.

FIG. 5: The same as Fig.1 but for ^{167}Lu .

Having confirmed that these features are independent of ϵ_2 and N except that we did not obtain any low-lying solutions for $35^\circ \lesssim \gamma \leq 60^\circ$ in the small- ϵ_2 cases, we look into underlying unperturbed 2QP energies to see the even-odd difference. In Fig.6 we present the energies of the lowest $(\pi(N_{\text{osc}} = 6))^2$ states which represent the biggest difference. In the yrast $(\pi i_{13/2})^2$ configuration, A_p and B_p in the usual notation are occupied in the even- Z case, the lowest 2QP state of signature $\alpha = 1$ with respect to this is $\bar{B}_p C_p$ (where $\bar{}$ denotes the conjugate state, see Eq.(4)). In the odd- Z case in which A_p is occupied, the lowest one is $B_p \bar{A}_p$. Since both e'_{B_p} and $e'_{\bar{A}_p}$ decrease as γ decreases, this 2QP state becomes the dominant component in the lowest-energy RPA solution. Note here that the sum $e'_{B_p} + e'_{\bar{A}_p}$ corresponds to the signature splitting between A_p and B_p when they are seen from the usual even-even vacuum. Since both B_p and $\bar{A}_p$ are of $K = 1/2$ character, the resulting RPA solution can

not have the $K = 2$ collectivity as shown in Fig.5(d). According to the relation [15],

$$\frac{\mathcal{J}_y^{(\text{eff})}}{\mathcal{J}_x} = \left[1 + \frac{\omega_{\text{wob}}}{\omega_{\text{rot}}} \frac{\sin \gamma}{\sin(\gamma + \frac{4}{3}\pi)} \frac{T_1}{T_2} \right]^{-1}, \quad (29)$$

$\mathcal{J}_y^{(\text{eff})}$ in Fig.5(b) becomes small for $-30^\circ \lesssim \gamma < 0$. This discussion serves to exclude the possibility of $\gamma \simeq -20^\circ$ for the TSDs that support collective wobbling excitations in the odd- Z cases, whereas the even-odd difference in $\gamma > 0$ is merely quantitative.

FIG. 6: Energies of the lowest $(\pi(N_{\text{osc}} = 6))^2$ two quasiparticle states in ^{168}Hf and ^{167}Lu , calculated at the same time as Figs.1 and 5, respectively.

C. Dependence on the rotational frequency ω_{rot}

1. ^{168}Hf and ^{174}Hf

The analyses above indicate that the chosen mean-field parameters are reasonable, and therefore we proceed to study ω_{rot} -dependence with keeping these parameters constant. Figure 7 shows the result for ^{168}Hf . These figures indicate again the $(\pi i_{13/2})^2$ alignment that makes $\mathcal{J}_x$ larger than $\mathcal{J}_y^{(\text{eff})}$ is indispensable for the formation of the wobbling excitation. At around $\hbar\omega_{\text{rot}} = 0.45$ MeV the $(\nu j_{15/2})^2$ alignment occurs. In contrast to the low-frequency case reported in Fig.3, in the present case its effect on ω_{wob} is visible as a small bump. Although the character of the observed excited TSD bands has not been resolved, some anomaly is seen at around this ω_{rot} in one of them [29]. We suggest this is related to the $(\nu j_{15/2})^2$ alignment since this is the only alignable orbital in this frequency region of this shape. However we note that in ^{167}Lu an interaction with a normal deformed state at around this frequency is discussed in Ref.[22].

We performed calculations also for $\gamma = -20^\circ$. In that case, however, wobbling excitation exists only at small ω_{rot} because $\mathcal{J}_x - \mathcal{J}_y^{(\text{eff})}$ is small as seen from Fig.1(b).

FIG. 7: Rotational frequency dependence of (a) excitation energy of the wobbling motion, (b) expectation values of angular momenta in the yrast state, and (c) three moments of inertia associated with the wobbling motion in ^{168}Hf , calculated with $\epsilon_2 = 0.43$, $\gamma = 20^\circ$ and $\Delta_n = \Delta_p = 0.3$ MeV.

Very recently TSD bands were observed in another even-even nucleus, ^{174}Hf [30]. It is not trivial if a similar band structure is observed in the nucleus with six neutrons more since the existence of the TSD states depends on the shell gap. Multiple TSD bands were observed but connecting γ -rays have not been resolved also in this nucleus. We performed a calculation adopting $\epsilon_2 = 0.453$ and $\gamma = 16^\circ$ suggested in Ref.[30] and $\Delta_n = \Delta_p = 0.3$ MeV. The result is presented in Fig.8. The most striking difference from the case of ^{168}Hf above is that ω_{wob} decreases steadily as ω_{rot} increases after the $(\pi i_{13/2})^2$ alignment is completed. This is because the $(\nu j_{15/2})^2$ alignment that causes the small bump in the ^{168}Hf case shifts to very low ω_{rot} due to the larger neutron number.

FIG. 8: Rotational frequency dependence of excitation energy of the wobbling motion in ^{174}Hf , calculated with $\epsilon_2 = 0.453$, $\gamma = 16^\circ$ and $\Delta_n = \Delta_p = 0.3$ MeV.

2. ^{167}Lu

The wobbling excitation was first observed experimentally in ^{163}Lu [19], later it was also observed in ^{165}Lu [21] and ^{167}Lu [22]. The characteristic features common to these isotopes are 1) ω_{wob} decreases as ω_{rot} increases contrary to the consequence of calculations adopting constant moments of inertia, and 2) $B(E2 : I \rightarrow I - 1)_{\text{out}}/B(E2 : I \rightarrow I - 2)_{\text{in}}$ is large — typically around 0.2.

Here we concentrate on the isotone of ^{168}Hf discussed above, that is, ^{167}Lu in order to see the even-odd difference. A comparison of Figs.7 and 9 proves that all the differences are due to the fact that the number of the aligned $\pi i_{13/2}$ quasiparticle is less by one: 1) The $(\pi i_{13/2})^2$ alignment at around $\hbar\omega_{\text{rot}} = 0.2$ MeV is absent, and 2) the $B_p C_p$ crossing occurs at around $\hbar\omega_{\text{rot}} = 0.55$ MeV, which is proper to the $(\pi i_{13/2})^1$ configuration. Figure 9(a) shows that our calculation does not reproduce the data, although in each frequency range in which the configuration is the same ω_{wob} decreases at high ω_{rot} as in the cases of the even-even nuclei presented above. This result might indicate that there is room for improving the mean field. The $\mathcal{J}_x$ in Fig.9(c) is larger than the experimentally deduced value by about 20 – 30 %. This is due to the spurious velocity dependence of the Nilsson potential mentioned in Sec.II.

D. Interband $B(E2)$ transitions

Compared to the excitation energy, the interband $B(E2)$ values relative to the in-band ones have been measured in only few cases. In Fig.10, we report calculated $B(E2)$ ratios

FIG. 9: The same as Fig.7 but for ^{167}Lu . Experimental values taken from Ref.[22] are also included in (a).

for I (wobbling on yrast TSD) $\rightarrow I \pm 1$ (yrast TSD) transitions in ^{168}Hf and ^{167}Lu . The measured ones are also included for the latter.

The first point is the magnitude of the larger ($I \rightarrow I-1$) ones. Apparently, the calculated $B(E2)$ values are smaller by factor 2 – 3. The measured interband $B(E2)$ values amount almost to the macroscopic rotor value. In the RPA calculations, as summarized in sect.II, the $B(E2)$ value is reduced by a factor $c_{n=\text{wob}}^2$ (see Eq. (24)): Only the case with the full-strength $c_{n=\text{wob}}^2 = 1$ the rotor value is recovered. Although the obtained RPA wobbling solutions are extremely collective in comparison with the usual low-lying collective vibrations, like the β - or γ -vibrations, for which typically $|c_n| \simeq 0.3 - 0.4$, this factor is still $|c_{n=\text{wob}}| \simeq 0.6 - 0.8$. This is the main reason why the calculated $B(E2)$ values are a factor 2 – 3 off the measured ones. As is well-known, giant resonances also carry considerable amount of quadrupole strengths, so it seems difficult for the microscopic correction factor $c_{n=\text{wob}}^2$ to be unity; it is not impossible, however, because the “sum rule” discussed in sect.II is not the sum of positive-definite terms. In the RPA formalism, the reduction factor $c_{n=\text{wob}}^2$ for the $B(E2)$ value, Eq. (24), comes from the fact that the wobbling motion is composed of the

coherent motion of two-quasiparticles, and reflects the microscopic structure of collective RPA solutions. The measurement that the $B(E2)$ value suffers almost no reduction may be a challenge to the microscopic RPA theory in the case of the wobbling motion. Calculated $B(E2)$ ratios for ^{174}Hf are slightly smaller than those for ^{168}Hf in Fig.10(a).

FIG. 10: Interband $E2$ transition rates for I (wobbling on yrast TSD) $\rightarrow I \pm 1$ (yrast TSD) transitions in (a) ^{168}Hf and (b) ^{167}Lu . The latter is presented as functions of $2 \times \text{spin } I$, while the former is presented as functions of the rotational frequency since experimental spin assignment has not been done for ^{168}Hf . The rotational-frequency range corresponding to (b) is very narrow in comparison to (a). Interband transition rates are divided by the in-band ones. Experimental values [22] are also shown in (b). Noting that, for ^{167}Lu , the states $I+1$ (TSD1) are slightly higher in energy than I (TSD2) at $I > 51/2\hbar$ and $B(T_{\lambda}; I \rightarrow I+1) \simeq B(T_{\lambda}; I+1 \rightarrow I)$ holds at high spins, we plotted those for $I \rightarrow I+1$ at the places with the abscissae $I+1$ in order to show clearly their characteristic staggering behavior.

The second point is the staggering, that is, the difference between $I \rightarrow I \pm 1$. We clarified [15] its unique correspondence to the sign of γ as mentioned in subsect.III B; that holds for both even-even and odd- A systems. Recently this staggering was discussed from a different point of view [31]; but it looks to apply only to $\gamma < 0$ cases.

IV. CONCLUSION

The nuclear wobbling motion, which is a firm evidence of stable triaxial deformations, was identified experimentally in the triaxial superdeformed odd- A Lu isotopes. In principle, wobbling excitation is possible both in $\gamma > 0$ and $\gamma < 0$ nuclei. Every information, theoretical

and experimental, suggests $\gamma > 0$ for these bands. According to the wobbling frequency formula [8], c.f. Eq.(12), its excitation in nuclei rotating principally about the x axis requires $\mathcal{J}_x > \mathcal{J}_y, \mathcal{J}_z$, although irrotational-like model moments of inertia give $\mathcal{J}_x < \mathcal{J}_y$ for $\gamma > 0$. To solve this puzzle, we studied the nuclear wobbling motion, in particular, the three moments of inertia associated with it in terms of the cranked shell model plus random phase approximation. This makes it possible to calculate the moments of inertia of the whole system including the effect of aligned quasiparticle(s). The results indicate that the γ -dependence of the calculated moment of inertia is basically irrotational-like ($\mathcal{J}_x \geq \mathcal{J}_y$ for $\gamma \lesssim 0$) if aligned quasiparticle(s) ($\pi i_{13/2}$ in the present case) does not exist. But once it is excited, it produces an additional contribution, $\Delta\mathcal{J}_x = i_{\text{QP}}/\omega_{\text{rot}}$, and consequently can lead to $\mathcal{J}_x > \mathcal{J}_y$. This is the very reason why wobbling excitation exists in $\gamma > 0$ nuclei. In this sense, the wobbling motion is a collective motion that is sensitive to the single-particle alignments.

The resulting moment of inertia for $0 < \gamma \lesssim 30^\circ$ resembles the γ -reversed one, i.e., the irrotational moment of inertia but with $\mathcal{J}_x$ and $\mathcal{J}_y$ being interchanged. That for $50^\circ \lesssim \gamma \lesssim 60^\circ$, where single-particle angular momenta dominate, is rigid-body-like. That for $\gamma < 0$ is irrotational-like except for odd- A nuclei with $-30^\circ \lesssim \gamma < 0$ where a specific 2QP state determines the lowest RPA solution.

Having studied qualitative features of the three moments of inertia at a low rotational frequency, we calculated wobbling bands up to high ω_{rot} . Experimentally they were confirmed only in odd- A Lu isotopes as mentioned above. The most characteristic feature of the data is that ω_{wob} decreases as ω_{rot} increases. This obviously excludes constant moments of inertia. In our calculation three moments of inertia are automatically ω_{rot} -dependent even when mean field parameters are fixed constant. It should be stressed that the wobbling-like solution in our RPA calculations is insensitive to the mean-field parameters, especially to the pairing gaps, as is shown in subsect.III B 1. This distinguishes the wobbling-like solution from the usual collective vibrations, which are sensitive to the pairing correlations. Thus, our microscopic RPA calculation confirms that the observed band is associated with a new type of collective excitation, although comparisons to the observed excitation energy indicate that there is room for improving the calculation.

As for the interband transition rates, our calculation accounted for only about one half or less of the measured ones, even though the wobbling-like solution is extremely collective

compared to the usual vibrational modes. This issue is independent of the details of choosing parameters. This confronts microscopic theories with a big challenge.
